I can open files which I have created using Python 3.4.4 but when I try to open the same files using Python 3 it throws up an error saying "TypeError: bad operand type for unary '-':str" What is the difference between these? A: 3 is the version in which most of the Python standard library was developed. It was frozen at that time. This means most of the stuff was available, but Python 3.x is not Python 2.x. In the docs of 3.4.4 it says "Python 3 compatibility", and from the release notes I can read that 3.4.4 adds support for Python 3.4, 3.5 and 3.6. 2 was frozen at a time when Python was developed heavily by people who were not familiar with type systems, and 2 does not support Unicode strings. In Python 3.x this is no longer a problem, because Python 3.x is also unicode compatible. On macOS however you cannot use 3.x. The Mac Python interpreter is Python 2.7 (and by the way it is based on the 2 series as well). If you use macOS, you'll need to install Python 2.7.9 or 2.7.10 from MacPorts or Homebrew respectively. You can then use both Python 2 and Python 3 in Mac OS X. A: Python 3 is a totally different language from Python 2. You can't use Python 2 code in Python 3. They are so different that Python 3 introduces a lot of new syntax. In Python 3, from sys import version_info. What does it do? First, it prints the string representation of sys.version, and second, it returns a tuple containing the numbers which represent version_info. So Python 3 prints something like Python 3
